## Hierarchical Methods and Sparse Grids – Archimedes' Quadrature in 1D –

Michael Bader  
Technical University of Munich

Summer 2022

# Why Numerical Quadrature?

Integration integral part in many applications, e.g.:

- Determine volumes (e.g. of beer/wine barrels)
- Option pricing (expectation values)
- Defuzzification for fuzzy controller
- Radiosity (accumulating light)
- discretization: Finite Volume/Finite Elements

Often no analytical solution available

⇒ Approximate solution: “**numerical quadrature**”

- Typical approach: approximate/interpolate, then integrate

Core-problem: representation of functions in several variables

- In **higher-dimensional settings** only stochastic (“Monte Carlo”, etc.) or hierarchical methods available
- Here: focus on hierarchical methods

# One-Dimensional Quadrature

## Approximations for the definite integral

$$F_1(f, a, b) := \int_a^b f(x) dx \quad \text{for } f : [a, b] \rightarrow \mathbb{R}$$

Context  $\rightsquigarrow$  approximation with piecewise linear/quadratic/. . . functions:

- We first consider classical methods  
→ Trapezoidal Rule
- Then hierarchical approach
- Assumption in the following: “ $f$  is sufficiently smooth”  
(i.e., all desired derivatives of  $f$  exist and are continuous)

# Trapezoidal Rule, Simpson Rule

## Classical methods for numerical quadrature: Newton-Cotes formulas

- $f(x_i)$  at equally spaced points  $x_i = a + ih$
- Integrate

$$\int_a^b f(x) \approx \sum w_i f(x_i)$$

- choose weights  $w_i$  such that integration is exact for polynomials up to a certain degree
- typically result from an interpolation problem

# Trapezoidal Rule, Simpson Rule

## Trapezoidal rule

- Interpolate at interval boundaries with linear function

$$F_1 \approx T := (b - a) \frac{f(a) + f(b)}{2}$$

## Simpson rule

- Interpolate at interval boundaries and midpoint with quadratic function

$$F_1 \approx S := (b - a) \frac{f(a) + 4f\left(\frac{a+b}{2}\right) + f(b)}{6}$$

# Quadrature Error

- Error terms are known for the two methods:

$$|T - F_1| \leq \frac{M_2}{12}(b-a)^3$$

$$|S - F_1| \leq \frac{M_4}{2880}(b-a)^5$$

- $M_2$  and  $M_4$  are bounds for the second, resp. fourth, derivative:

$$M_2 := \sup_{x \in [a,b]} |f''(x)|,$$

$$M_4 := \sup_{x \in [a,b]} |f^{(4)}(x)|.$$

$\Rightarrow$  assumes that these derivatives and such bounds exist!

# Composite Quadrature Rules

- Error bounds suggest the following improvement:
  - Split interval  $[a, b]$  into smaller subintervals
  - Apply simple quadrature rule in each of them
- Simplest case:  
choose uniform grid with  $n$  intervals and mesh-width  $h = (b - a)/n$
- Composite trapezoidal rule

$$CT := h \cdot \left[ \frac{f(a)}{2} + \sum_{i=1}^{n-1} f(a + ih) + \frac{f(b)}{2} \right]$$

- Composite Simpson's rule

$$CS := \frac{h}{6} \left[ f(a) + 4f\left(a + \frac{h}{2}\right) + 2f(a + h) + 4f\left(a + \frac{3h}{2}\right) \right. \\ \left. + \dots + 4f\left(b - \frac{h}{2}\right) + f(b) \right]$$

## Composite Quadrature Rules – Error

- To measure the error: sum up  $n = (b - a)/h$  terms (one for each interval)
- Terms are in  $\mathcal{O}(h^3)$  and  $\mathcal{O}(h^5)$  resp.

$$|CT - F_1| \leq \frac{M_2}{12}(b - a) \cdot h^2,$$

$$|CS - F_1| \leq \frac{M_4}{2880}(b - a) \cdot h^4.$$

- Accuracy increases with  $n$
- Doubling the computational effort ( $h \rightsquigarrow h/2$ ) reduces error bound to  $1/4$  (CT) and  $1/16$  (CS), if  $f$  is sufficiently smooth

# Composite Quadrature Rules – Summary

## Typical non-hierarchical methods

- Summands have (more or less) same weight
- To store: use array
- To implement: use for-loop
- To increase accuracy: discard old result, start all over once again

## What we desire:

- Allow “adaptive” choice of  $h$ : fine where required, coarse where possible
- Availability of an “error indicator”: where do we need fine resolution?

# Archimedes' Hierarchical Approach

(to compute the area under a parabola)

We now decompose the area  $F_1$  in a **hierarchical manner**:

- Start with trapezoid as for trapezoidal rule:

$$T_1(f, a, b) = \frac{b-a}{2}(f(a) + f(b)).$$

- Let remaining error term (area between trapezoid and curve) be  $S_1$ :

$$F_1(f, a, b) = T_1(f, a, b) + S_1(f, a, b).$$

- Hierarchical approach if current approximation too inaccurate:
  - Take trapezoid (intermediate solution)
  - Add approximation for  $S_1$

## Decomposition of Remainder $S_1$

- Decompose remainder  $S_1$  into triangle  $D_1$  with (projected) base  $(b - a)$  and height

$$f\left(\frac{a+b}{2}\right) - \frac{f(a) + f(b)}{2} :$$

$$D_1(f, a, b) = \frac{b-a}{2} \left( f\left(\frac{a+b}{2}\right) - \frac{f(a) + f(b)}{2} \right)$$

- We obtain two remainders of similar type

$$S_1(f, a, b) = D_1(f, a, b) + S_1(f, a, \frac{a+b}{2}) + S_1(f, \frac{a+b}{2}, b)$$

- Both are typically much smaller!

# Recursive Computation of $F_1$

- Interpret formulas for  $F_1$  (area below curve),  $T_1$  (trapezoid) and  $S_1$  (remainder) as function definitions
- ⇒ Obtain recursive method to compute  $F_1$

## Stopping criterion

- Note: recursion does not terminate so far
- As we're only interested in approximation:  
implement termination criterion in function  $S_1$ , for example
  - Count recursion depth ( $t = 0$  for whole interval  $[a, b]$ ,  
 $t = 1$  for the first two subintervals, ...)
  - Stop recursion for certain  $t = l$
  - Then we exactly compute the composite trapezoidal quadrature for  $n = 2^l$
  - Alternatively, we could have used  $b - a \leq h$  for some  $h = 2^{-l}$  as stopping criterion

# Adaptive Stopping Criterion

- Intuitive assumption (look at drawings): triangle  $D_1$  comprises most of  $S_1$
  - Later, we'll see that  $D_1$  covers  $3/4$  of the area of  $S_1$  for sufficiently smooth functions and asymptotically for small  $h$
  - We can hope (but not be sure!):  
*Error for the computation of  $S_1$  is about  $D_1/3$  when stopping the recursion*
  - Hierarchical approach provides a stopping criterion for free
- ⇒ We can control the error of the quadrature!
- Even better:
    - Take height of triangle (*hierarchical surplus*) instead of area
    - Stop if smaller than some  $\epsilon$
- ⇒ We can hope to bound global error (w.r.t.  $F_1$ ) by  $\epsilon \cdot (b - a)$

# Archimedes' Quadrature – Summary

## Algorithm:

1. compute area as sum of trapezoid and remaining segment:

$$F_1(f, a, b) = T_1(f, a, b) + S_1(f, a, b) = \frac{b-a}{2}(f(a) + f(b)) + S_1(f, a, b)$$

2. compute area of triangular surplus:

$$D_1(f, a, b) = \frac{b-a}{2} \left( f\left(\frac{a+b}{2}\right) - \frac{f(a)+f(b)}{2} \right)$$

3. terminate, if surplus or  $D_1(f, a, b)$  is smaller than  $\epsilon$
4. otherwise, recursively compute remaining segment:

$$S_1(f, a, b) = D_1(f, a, b) + S_1\left(f, a, \frac{a+b}{2}\right) + S_1\left(f, \frac{a+b}{2}, b\right)$$

## Some Remarks

- For polynomials  $f$  of degree 2 (i.e., parabolas), we can compute (exactly)

$$D_1 = \frac{3}{4} S_1$$

- When stopping the recursion, we can take  $4/3 \cdot D_1$  rather than  $D_1$   
⇒ We obtain the integrand exactly
- Without adaptivity: computes the composite Simpson's rule

### Improved Recursive Scheme:

- Currently: 3 evaluations of  $f$  to compute the hierarchical surplus
  - When calling function  $S_1$ , we have already computed  $f$  at the interval boundaries
- ⇒ Extend recursive call  $S(f, a, b)$  to  $S(f, a, b, f(a), f(b))$  at no extra cost
